7

8 **Abstract.** Using the NEODAAS-Dundee AVHRR receiving station (Scotland), NEODAAS-Plymouth can
9 provide calibrated brightness temperature data to end users or interim users in near-real time.
10 Between 2000 and 2009 these data were used to undertake volcano hot spot detection, reporting
11 and time-average discharge rate dissemination during effusive crises at Mount Etna and Stromboli
12 (Italy). Data were passed via FTP, within an hour of image generation, to the hot spot detection
13 system maintained at Hawaii Institute of Geophysics and Planetology (HIGP, University of Hawaii at
14 Manoa, Honolulu, USA). Final product generation and quality control was completed manually at
15 HIGP once a day, so as to provide information to onsite monitoring agencies for their incorporation
16 into daily reporting duties to Italian Civil Protection. We here describe the processing and
17 dissemination chain, which was designed so as to provide timely, useable, quality-controlled and
18 relevant information for “one voice” reporting by the responsible monitoring agencies.

19

20 **Introduction**

21 The 1980’s saw a number of studies that used Advanced Very High Resolution Radiometer (AVHRR)
22 mid-infrared (MIR) and long-wave infrared (TIR) data to detect, track and measure the spatial and
23 temporal occurrence of natural fires and anthropogenic hot spots, such as those associated with oil
24 platforms and industry (e.g., Matson and Dozier, 1981; Muirhead and Cracknell, 1984; 1985). In her
25 review, “*Fire from space: Global fire evaluation using infrared remote sensing*”, Robinson (1991)
26 listed 14 papers that focused on such efforts using AVHRR data between 1980 and 1989, to which a
27 15th can be added: the study of Dozier (1980) (Table 1). As part of these efforts, the decade spanning
28 1985 to 1995 saw the development of a number of algorithms to detect wild fires in AVHRR, as well
29 as GOES-Imager, data. Table 2 flags the paper of Flannigan and Vonder Haar (1986) as the first

30 publication of an automated fire detection algorithm, where we then tabulate 11 different
31 algorithms developed during following nine years, with a 12th – the “*Contextual algorithm for AVHRR*
32 *fire detection*” of Flasse and Ceccato (1996) – being published in 1996.

33 Algorithms used to detect hot spots in satellite-sensor data, as developed by the fire and
34 volcanological communities, can be split into three classes depending on way in which the algorithm
35 defines a hot spot (Steffke and Harris, 2011). Fixed threshold algorithms use single or multiple test
36 and thresholds to determine whether a pixel is hot or not, assessing whether the target pixel’s
37 spectral character flags it as anomalously hot. Contextual algorithms assess the pixel’s spatial
38 context, using statistics from the target pixel’s immediate image background to assess whether the
39 pixel brightness is significantly different from that of its surrounding pixels or not. Finally, temporal
40 algorithms assess whether the pixel brightness is significantly different from that of its preceding
41 history, thus determining whether a pixel is thermally anomalous in a temporal sense. As a result of
42 the work reviewed in Tables 1 and 2, the fire community had defined the basis of fixed threshold and
43 contextual algorithms by 1995. Of the algorithms collated in Table 2, seven algorithms were fixed
44 threshold and five were contextual. These fire detection algorithms, and their physical basis,
45 underpinned many of the volcanic hot spot detection algorithms that followed. Importantly, the
46 concept of ΔT was established by the fire community, being used by seven of the algorithms of Table
47 2. That is, the differing sensitivities of the MIR and TIR to a sub-pixel hot spot will mean that the
48 pixel-integrated temperature for the hot-spot pixel will be higher in the MIR than in the TIR. In the
49 example given by Harris (2013), a 2 m radius volcanic vent at 950 °C is set against a 0 °C background
50 in a 1000 m AVHRR pixel, with solar-heated pixels being apparent lower on the volcanoes flanks at
51 40 °C. For this case, the MIR pixel-integrated temperature (T_{MIR}) is 11 °C, but in the TIR the pixel-
52 integrated temperature (T_{TIR}) is 0.04 °C, i.e., colder than the pixels lower on the volcanoes flanks at
53 40 °C. However, if we subtract the brightness temperature in the TIR from that in the MIR we have a
54 difference ($\Delta T = T_{MIR} - T_{TIR}$) of ~10 °C. If we take the surrounding solar heated pixels at 40 °C, the
55 temperature will be approximately the same in both wavebands, so that ΔT is ~0 °C. Now, the hot
56 spot that was not resolvable using one waveband of data becomes resolvable using ΔT . That is, it
57 shows up as a value of 10 °C against a flat background of near-zero values.

58 Based on advances made by the fire community, the first automated detection algorithm for volcanic
59 hot spots, the VAST (Volcanic Anomaly SoftWare) code of Higgins and Harris (1997), was introduced
60 in 1995 (Harris et al., 1995a). Written in ANSI C and made generally available through download
61 from the *Computers & Geosciences* web-site, VAST was initially tested on AVHRR data for Etna and
62 later on AVHRR data for Australian wild-fires burning around Sydney (Harris, 1996). VAST was a

63 contextual algorithm that used ΔT . Shortly thereafter, the first temporal algorithm – the Robust
64 AVHRR Techniques (RAT) algorithm – came on-line (Tramutoli, 1998). Later renamed the Robust
65 Satellite Technique (RST) the algorithm relied on an archive of MIR data to create an Absolutely Local
66 Index of Change of Environment (ALICE) (Pergola et al., 2008; 2009). ALICE provided an estimate of
67 how much a pixel brightness diverged from its normal conditions as determined from the data time
68 series, normalized for its natural variability in the time domain so as to detect temporally anomalous
69 behavior including volcanic hot spots (e.g., Di Bello et al. 2004). In 2000, the now widely-used
70 MODVOLC system became operational (Flynn et al., 2002; Wright et al., 2002). Based on a detection
71 routine that used a fixed threshold algorithm based on the ΔT principle, the normalized thermal
72 index (NTI), MODVOLC provided a simple global hot spot detection capability that required a minimal
73 number of mathematical operations (Wright et al., 2002; 2004). Thus, as of 2000, a number of
74 volcano hot spot satellite-sensor detection and reporting systems were operational, including the
75 Okmok algorithm (Dehn et al., 2000). This was developed at the Alaska Volcano observatory (AVO)
76 to aid with operational hot spot detection in AVHRR data. As part of the AVO function, over 100
77 volcanoes across Alaska, the Aleutians, Kamchatka, and the northern Kurile islands were monitored
78 in as close-to-real-time-as-possible using direct reception of AVHRR, GOES and GMS data at a
79 receiving station installed at the University of Alaska (Fairbanks) in 1990 (Dean et al., 1996; 1998).
80 We here explore the implementation and utility of an operational satellite-sensor based hot spot
81 detection and tracking system launched in 2000 and still, like the MODVOLC system, operational
82 today.

83 The Natural Environment Research Council (NERC) Earth Observation Data Acquisition and Analysis
84 Service (NEODAAS) is funded by NERC to support UK research scientists with remote sensing data
85 (<http://www.neodaas.ac.uk/>). The service has the capability to automatically receive, process, and
86 archive data from multiple polar-orbiting sensors, including MODIS and AVHRR, in near-real time.
87 Data are also received and processed from multiple geostationary satellites, including SEVIRI, VISSR,
88 GOES and MTSAT (Groom et al., 2006). Between 2000 and 2009, AVHRR data supplied in near-real
89 time by NEODAAS were used to communicate hot spot information during effusive crises at Mt. Etna
90 and Stromboli (Italy). We here describe this data reception, processing and communication chain.

91

92 **The satellite data: reception and pre-processing**

93 The NEODAAS service is hosted at two sites. While data reception and acquisition is provided by the
94 Dundee Satellite Receiving Station at the University of Dundee (NEODAAS-Dundee), data processing
95 is provided by the Remote Sensing Group at the Plymouth Marine Laboratory (NEODAAS-Plymouth).

96

97 NEODAAS-Dundee

98 During the 1970s, an AVHRR receiving station was developed at the University of Dundee. Data were
99 archived onto magnetic tapes and a quick-look image archive was maintained, and updated daily, in a
100 photographic format filed in ring-binders. During the 1990s raw data could be ordered on magnetic
101 tape, but delivery delays were of the order of weeks. However, archived AVHRR data were used to:

- 102 1. Test initial hot spot detection algorithms (Harris et al., 1995a; Pergola et al., 2001);
- 103 2. Track effusive eruptions through spatial and temporal analysis of spectral radiance (Harris et
104 al., 1995b, 1997a; Tramutoli et al., 2001);
- 105 3. Develop means for time-averaged discharge rate extraction (Harris et al., 1997b; Harris and
106 Neri, 2002); and
- 107 4. Define and understand detector response problems over high temperature targets (Setzer
108 and Verstraete, 1994; Harris et al., 1995c).

109 All data received by NEODAAS-Dundee are processed in near-real time and made available on-line.
110 These are automatically added to the online archive, whose sensor and data base coverage is
111 summarized in Table 3. Currently, AVHRR, MODIS and MSG data are received directly at NEODAAS-
112 Dundee and two products are generated:

- 113 • Level 0: unprocessed instrument data;
- 114 • Level 1: geolocated unprocessed instrument data including calibration parameters.

115 For AVHRR, coverage extends from Newfoundland to Moscow and from North Africa though
116 Greenland (Figure 1a). Image frequency depends on location (Figure 1b), with up to five images a
117 day being available for Etna, although at-least two may be close to the scan edge and, although
118 useful for event detection, are potentially difficult to use quantitatively (Harris et al., 1997b).

119

120 NEODAAS-Plymouth

121 During the 1990s, the Plymouth Marine Laboratory (at the time operating under the auspices of the
122 Remote Sensing Data Analysis Service) provided calibration coefficients for conversion from DN to
123 spectral radiance, upon agreement. Also provided were on-board blackbody temperatures,

124 necessary for non-linear correction of the conversion. Today, direct-broadcast data received at
125 Dundee are transferred over the internet to Plymouth where higher level processing is undertaken.
126 AVHRR data are processed into sea-surface temperature following Miller et al. (1997), and MODIS
127 data are processed into ocean color and atmospheric products (Shutler et al., 2005); typically 1-2
128 hours after reception (Groom et al., 2006). Global coverage is available from NASA and ESA sourced
129 data and from geostationary archives for Meteosat, MSG, IODC, GOES-East, GOES-West and MTSAT.
130 Data are processed to provide three further levels of product:

- 131 • Level 2: derived variables, such as vegetation indices, sea surface temperature, ocean color
132 and atmospheric properties;
- 133 • Level 3: temporally or spatially binned level 2 data, such as daily, weekly or monthly
134 composites for a single product or region;
- 135 • Level 4: derived from multiple measurements or models – e.g., ocean front analyses.

136 Third party (user-specified) products can also be generated. Quick look browse of all products are
137 made available via the internet as quickly as possible, with ftp access to products and data being
138 made available to registered users at the same time.

139

140 **Data sets for hot spot detection: The role of AVHRR**

141 Across the infrared spectral region (0.7 – 20 μm) there are eight atmospheric windows within which
142 atmospheric transmission is greater than 90 % (Table 4). Hence, wavebands for Earth-surface
143 thermal applications need to be placed in these spectral regions if the surface emission properties
144 are to be measured from the in-orbit location (i.e., above the top of the atmosphere). Following
145 Wein’s displacement law, channels placed in the MIR, between 3.44 and 4.13 μm , and in the TIR,
146 between 8.6 and 12.2 μm , will be most sensitive to surfaces at elevated temperatures (fires and
147 active lavas) and typical Earth surface ambient temperatures, respectively (Table 4). The two
148 wavebands have thus respectively been used for measurements of the two surface types, with the
149 extreme sensitivity of the 3.44 to 4.13 μm waveband to sub-pixel hot spots meaning that it has
150 become informally termed the “fire channel” (e.g., Vermote et al., 2009).

151 AVHRR’s channel 3 has been long known to be extremely sensitive to, and thereby capable of,
152 detecting small, high temperature sub-pixel heat sources, such fires due to straw burning and gas
153 flares on oil platforms (Matson and Dozier, 1981; Muirhead and Cracknell, 1984; 1985). However,
154 AVHRR’s channel 3 also has a saturation temperature of between 50 and 60 $^{\circ}\text{C}$, so that data saturate

[Titre du document]

155 quite easily over sub-pixel fire and volcanic hot spots (Setzer and Verstraete, 1994; Harris et al.,
156 1995c). Solutions have, though, been found to work around this problem and unsaturated thermal
157 data are usually available over hot spots in AVHRR's two TIR, channels 4 (10.3 – 11.3 μm) and 5 (11.5
158 – 12.5 μm). In addition, AVHRR data represent the longest continuous meteorological satellite data
159 set, with the NEODAAS MIR and TIR archive dating back to the first launch of AVHRR on TIROS-N in
160 October 1978. If we consider the AVHRR's predecessor, the Very High Resolution Radiometer, the
161 TIR data set can be extended back to first launch on NOAA-2 in November 1972 (Cracknell, 1997). As
162 of 2015, these archives potentially provided a 43-year-long base-line data set, which for equatorial
163 targets has a nominal temporal resolution of four images per day, increasing to 10 or more towards
164 the poles due to convergence of orbits (Harris et al., 1999). Pixels increase in size from, for channel
165 3B on NOAA's -15, -16 and -17, 1.11 km and circular at nadir to 7.9×2.6 km (oblate ellipse) at the
166 edge of the 3000 km wide scan. Pixels will also undergo distortion, become rotated, and become
167 heavily overlapped towards the edge of the $\pm 55.4^\circ$ wide swath. However these effects can be
168 assessed and corrected for (Harris, 2013). Because of AVHRR's utility and longevity, as of 2005
169 AVHRR accounted for 47 (or 39 %) of the 120 studies published within the field of satellite-sensor
170 based detection, tracking and measurement of volcanic hot spots since 1965 (Harris, 2013).

171 As Robinson (1991) pointed out, although AVHRR was designed for meteorological observations,
172 channel 3 was somewhat "serendipitously well placed" to detect hot spots. However, the utility of 1-
173 km satellite-based measurements in the MIR for fire and volcano hot spot studies have led to some
174 sensors, such as MODIS and BIRD, being designed with a high gain setting channel at 3.9 μm (that
175 saturates at temperatures of up to 400-450 K) with the fire community specifically in mind (e.g.,
176 Kaufman et al., 1998; Wooster et al., 2003). In addition, 3.9 μm channels on geostationary satellites,
177 such as the Imager on GOES and SEVIRI on Meteosat, have long proved capable of tracking hot spots
178 due to fires at temporal resolutions of 15 minutes or better, in spite of having 3-4 km pixels (e.g.,
179 Prins and Menzel, 1994; Roberts and Wooster, 2008). Consequently, the high temporal resolution
180 and "fire channel" detection capability offered by sensors mounted on geostationary platforms have
181 proved to be of extreme utility for short-lived effusive events or activity varying over time-scales of
182 10's of minutes, such as activation and deactivation of active fissure segments (e.g., Harris et al.,
183 1997c; Harris and Thornber, 1999; Ganci et al., 2012). Such events may be missed, or just imaged
184 once or twice, by the polar orbiters that carry sensors with thermal capabilities which have return a
185 period of 6-12 h. As a result, today, although NOAA NESDIS (2015a) state that the objective of the
186 AVHRR instrument is to:

[Titre du document]

187 “provide radiance data for investigation of clouds, land-water boundaries, snow and ice
188 extent, ice or snow melt inception, day and night cloud distribution, temperatures of
189 radiating surfaces, and sea surface temperature;”

190 added is:

191 “In addition, land use applications of the AVHRR include monitoring of: food crops; **volcanic**
192 **activity**; forest fires; deforestation; vegetation; snow cover; sea ice location; desert
193 encroachment; icebergs; oil prospecting and geology applications. Other miscellaneous
194 AVHRR applications include the monitoring of: migratory patterns of various animals; animal
195 habitats; environmental effects of the Gulf War; oil spills; locust infestations; and nuclear
196 accidents such as Chernobyl.”

197 Thus, volcano monitoring has become established and recognized as part of the application of NOAA
198 NESDIS data. In this regard, following NOAA NESDIS (2015b), NESDIS is currently,

199 “dedicated to providing timely access to global environmental data from satellites and other
200 sources to promote, protect and enhance the Nation's economy, security, environment and
201 quality of life.”

202 In terms of compatibility with volcano monitoring, the NOAA NESDIS mission is to (NOAA NESDIS,
203 2015b):

- 204 (i) manage operational environmental satellites,
- 205 (ii) operate the NOAA National Data Centers,
- 206 (iii) provide data and information services including Earth system monitoring,
- 207 (iv) perform official assessments of the environment, and
- 208 (v) conduct related research.

209 AVHRR will thus likely continue to be a robust and reliable resource for volcano hot spot monitoring
210 for the fore-seeable future, providing a data base that has its foundations in 55 years of technological
211 and applicative development. As of 2015, six AVHRR sensors were in orbit aboard NOAA's -14
212 through -19. Although “old”, the first satellite in the series having been launched on 1 April 1960
213 carrying the Vidicon sensor (Cracknell, 1997), the series is by no means obsolete, and is constantly
214 being upgraded,

[Titre du document]

215 “to support a complete meteorological payload plus the necessary support subsystems to
216 meet all interface and system requirements” (Robel, 2009).

217 At the same time,

218 “NOAA has tried to keep the changes to a minimum” (Robel, 2009)

219 so as to maintain the continuity of service and the “digital archive of data collected from the current
220 generation of NOAA operational polar orbiting satellites” (Kidwell, 1998).

221 The series thus provides a reliable MIR and TIR data set adding, at minimum, four extra 1-km spatial
222 resolution observation data points to an ensemble-based approach that can over up to 16 “looks”
223 per day if we combine NOAA+METOP+TERRA+AQUA capabilities (Harris et al., 2015). What’s more,
224 the service us underwritten by NOAA, providing continuity of data and a reliable resource.

225

226 **Tools used for hot spot tracking**

227 AVHRR data provided by NEODAAS-Plymouth for Italy and Iceland were ingested into the Hawaii
228 Institute of Geophysics and Planetology (HIGP) hot spot tracking system. From 2000 onwards, the
229 system ingested near-real time GOES-Imager data to track hot spot activity around the Pacific Rim
230 (Harris et al., 2000a; 2001; 2002a; 2002b), and was linked to the MODVOLC tool. The system
231 produced a number of quick-look image products. These were generated on-the-fly so as to reduce
232 storage space, meaning that only raw data were saved, and then used to generate products from the
233 archive. A rolling text-file data base, containing basic locational and radiance data for each target
234 region of interest (ROI) was also updated with each image acquisition. The same system
235 automatically generated an email notice if the probability of any pixel in a ROI exceeded a threshold,
236 linking the recipient to the image products for image that generated the notice (Harris et al., 2002a).
237 This initial threshold was based on a multistep, fixed threshold approach (Table 5) which operated
238 along the lines of the fire detection algorithms given in Table 2. For the NEODAAS-Plymouth AVHRR
239 data, this algorithm was used purely for issuance of email notices which the recipient used to check
240 the veracity of a “detected” hot spot. If the hot spot was valid, then the operator proceeded
241 manually by checking all images to precedent to the notice so as to ascertain the exact start time
242 (within the temporal resolution of the sensor) of the event. Operator analysis continued by checking
243 each new image until the event was over. Manual checking initially involved detecting and logging
244 anomalous pixels by eye. Later hot pixel detection and selection was guided by application of an up-
245 dated version of VAST. Pixel radiance values were then converted to useable (by the field

246 volcanologist and hazard responder) metrics in a timely fashion, these metrics primarily being time
247 and Time-Averaged Discharge Rate (TADR).

248

249 Manual checking: NEODAAS-Plymouth quick-look hot spot tool

250 NEODAAS-Plymouth maintains a quick-look hot spot tool at
251 <https://www.neodaas.ac.uk/supportedscience/etna.php> (Figure 2). The tool involves an enhanced
252 AVHRR channel 3 image of Sicily (including the Aeolian Islands) and Iceland. Enlargements of both
253 the channel 3 and channel 4 images for Etna are inset into the overview image. The most recent
254 image is given, along with all images acquired during the preceding week. The current image is
255 updated as soon as new data arrive, and the archive can be browsed using forward and backward
256 buttons at the top of the tool. This simple, but effective, system allows the presence of thermal
257 anomalies to be checked by virtue of their intense radiance in channel 3 and, if sufficiently intense, in
258 channel 4 also, as in the case given in Figure 3.

259 As argued by Harris (2013), visual detection using time series of such images remains the most
260 powerful and trustworthy tool for hot spot detection and tracking. That is,

261 “by examining multiple images of the same volcano target we train a powerful neural
262 network for hot spot detection. In some subtle detection cases it may even be difficult for
263 the operator to describe the detection algorithm they have sub-consciously developed, for
264 the detection is based upon the most complex of neural networks.”

265 In the case of Figure 3, the presence of hot spots due to volcanic activity on Mt. Etna is immediately
266 apparent to the eye. Hence, manual checking – and tools that allow such interaction – remain the
267 most bullet-proof way to ensure that: (i) the hot spot is valid, (ii) all pixels required for complete
268 quantitative analysis are selected, and (iii) no spurious pixels are included.

269

270 Automated checking: VAST-II

271 VAST’s implementation is based on the concept of “*natural variation*” (Harris et al., 1995a). This was
272 defined as the difference between a pixel’s brightness and that of its surroundings, as defined by the
273 eight pixels immediately surrounding the target pixel (Figure 4). Although over thermally
274 homogeneous surfaces, such as the sea, natural variation should be close to zero; over thermally
275 heterogeneous surfaces, natural variation should be highly variable (and typically greater than 10 °C).

276 The updated version of VAST used to guide pixel selection in NEODAAS-Plymouth AVHRR data
277 functioned in the same way as the original version, but used the TIR brightness temperature (T_{TIR})
278 image, rather than the ΔT image, a modification which allowed application when MIR data was
279 lacking. The new version of VAST also allowed user interaction so that anomalous pixels not flagged
280 by the algorithm could be selected or false positives de-selected (Steffke and Harris, 2011).

281 A 30×30 AVHRR pixel target window was centered at $37.37^\circ N$, $15.00^\circ E$, the size of which could be
282 altered by the operator. Natural variation ($\bar{\omega}$) was then defined for all pixels in the image. An image-
283 specific natural variation threshold ($\bar{\omega}_{thresh}$) was set from the “non-volcanic” portion of the sub-image,
284 this being a 5 pixel wide strip running around the target window, the size of which could also be
285 enlarged or reduced by the operator. The value for $\bar{\omega}_{thresh}$ was set equal to the maximum $\bar{\omega}$ found
286 within the “non-volcanic” zone. Then, if $\bar{\omega}$ for a pixel in the target window was greater than $\bar{\omega}_{thresh}$, it
287 was flagged as anomalous. For pixels at the center of a large anomaly $\bar{\omega}$ might be quite low due to all
288 surrounding ΔT or T_{TIR} values being high. Thus, anomalous pixels located in the first run were
289 masked, the $\bar{\omega}$ value for each pixel recalculated with hot pixels flagged in the first run excluded, and
290 the test re-run. This process was iterated until no new pixels were found (Harris et al., 1995a).
291 Location and spectral radiance vales for detected pixels – as confirmed, rejected or added by the
292 operator – were then exported to a data file and used for conversion to TADR.

293

294 Conversion to TADR

295 Following Wright et al. (2001), lava area obtained from satellite-sensor IR data can be converted to
296 time-averaged discharge rate following a linear relation:

297
$$TADR = x A_{lava} \tag{1}$$

298 A_{lava} being the area of active lava, and x being the slope of the linear relation between TADR and A_{lava}
299 for the case in hand (Harris and Baloga, 2009). The satellite-data-derived variable in this relation is
300 A_{lava} , which we derived as follows:

301 1. AVHRR channel 3 and channel 4 spectral radiances R_{3-int} and R_{4-int} were recorded for
302 all detected hot spot pixels (Figure 5).

303 2. Atmospheric and emissivity corrections were applied to all selected radiances, i.e.,

304 In channel 3: $R_{3-int-corr} = (R_{3-int} - R_{reflec}) / \epsilon_{\lambda 3} \tau_{\lambda 3} \tag{2a}$

305 In channel 4: $R_{4-int-corr} = (R_{4-int} - R_{upwell}) / \epsilon_{\lambda 4} \tau_{\lambda 4} \tag{2b}$

306 In which ϵ and τ are the surface emissivity and atmospheric transmissivity in the two
 307 wavebands centered at wavelengths λ_3 and λ_4 , respectively. R_{reflec} is the surface
 308 reflected spectral radiance that contributes to the at-sensor pixel-integrated spectral
 309 radiance in channel 3, and R_{upwell} is the atmospherically-emitted spectral radiance
 310 that contributes to the at-sensor pixel-integrated radiance in channel 4.

- 311 3. For each hot spot pixel, a background radiance (R_{back}) is selected from the nearest,
 312 non-hot spot, pixel of lowest radiance (Figure 6).
- 313 4. Because AVHRR channel 3 is usually saturated over a volcanic (or fire) hot spots
 314 (Harris et al., 1995c), only one channel is useable – channel 4 (i.e., R_{4-int} and R_{4-back} ;
 315 which when corrected for emissivity and atmospheric effects are $R_{4-int-corr}$ and
 316 $R_{4-back-corr}$). Thus we are forced to apply a one-waveband method (Harris et
 317 al.1997a,b; Harris, 2013) so that channel 4 spectral radiances are used in a two
 318 component mixture model to obtain the portion of the pixel occupied by the hot
 319 source (p):

$$320 \quad p = (R_{4-int-corr} - R_{4-back-corr}) / (R_{4-hot} - R_{4-back-corr}) \quad (3)$$

321 in which R_{4-hot} is the spectral radiance emitted by the hot (active lava) source resident
 322 in the pixel. Due to uncertainty and real variability in the exact value of R_{4-hot} , this
 323 value has to be assumed over a range, where the spectral radiance equivalents of the
 324 temperature limits 100 °C and 600 °C have been found appropriate for active lava at
 325 Etna, Stromboli and Iceland (Harris et al., 2007; Harris and Baloga, 2009; Harris,
 326 2013). This gives two values for p :

- 327 (i) a maximum value (p_{max}) obtained with the low temperature assumption (T_l),
 328 (ii) a minimum value (p_{min}) obtained with the high temperature assumption (T_h).

- 329 5. Next, pixel area (A_{pixel}) is calculated as a function of scan angle. This is multiplied by
 330 p_{max} and p_{min} to obtain a range of estimates for the area of active lava resident in the
 331 pixel (A_{lava-p}):

$$332 \quad A_{lava-p-max} = p_{max} A_{pixel} \quad (T_l = 100 \text{ °C}) \quad (4a)$$

$$333 \quad A_{lava-p-min} = p_{min} A_{pixel} \quad (T_h = 600 \text{ °C}) \quad (4b)$$

334 Results for all hot spot pixels are summed to obtain a maximum and minimum bound
 335 on the total area of active lava at the imaged eruption site ($A_{lava-max}$ and $A_{lava-min}$).

- 336 6. Finally, to obtain the limits on TADR, the two lava area estimates are placed into two
 337 empirically-derived conversion routines tailored for the case in hand (Harris et al.,
 338 2010). For the period 2000-2009 at Etna the following conversions were found to

[Titre du document]

339 produce the best-empirical fit between model output and ground truth (Harris et al.,
340 2011):

$$341 \quad \text{TADR}_{\min} (\text{m}^3 \text{s}^{-1}) = 5.5 \times 10^{-6} (\text{m s}^{-1}) A_{\text{lava-max}} (\text{m}^2) \quad (T_l = 100 \text{ }^\circ\text{C}) \quad (5a)$$

$$342 \quad \text{TADR}_{\max} (\text{m}^3 \text{s}^{-1}) = 150 \times 10^{-6} (\text{m s}^{-1}) A_{\text{lava-min}} (\text{m}^2) \quad (T_h = 600 \text{ }^\circ\text{C}) \quad (5b)$$

343 For Stromboli, we obtained (Calvari et al., 2005):

$$344 \quad \text{TADR}_{\min} (\text{m}^3 \text{s}^{-1}) = 2.5 \times 10^{-6} (\text{m s}^{-1}) A_{\text{lava-max}} (\text{m}^2) \quad (T_l = 100 \text{ }^\circ\text{C}) \quad (6a)$$

$$345 \quad \text{TADR}_{\max} (\text{m}^3 \text{s}^{-1}) = 166 \times 10^{-6} (\text{m s}^{-1}) A_{\text{lava-min}} (\text{m}^2) \quad (T_h = 600 \text{ }^\circ\text{C}) \quad (6b)$$

346 *Uncertainty*

347 Two TADR values are thus output: one each for the maximum and minimum bound on the derived
348 A_{lava} which, in turn, results from uncertainty in (or impossibility of) applying a single temperature
349 value to describe the thermal surface structure of the lava active within the pixel. As is standard, the
350 uncertainty range lies between the highest possible temperature that can realistically be assigned to
351 this source (T_h) and the lowest (T_l). If the conversion is appropriately set and applied, output TADR
352 have been shown to span the range of field-based estimates (Calvari et al., 2005; 2010; Harris et al.,
353 1997a,b; 2007; 2011; Harris, 2013), while also (on occasion) giving a smaller range of uncertainty
354 than field-based estimates made under similar, near-real time, requirements (e.g., Harris and Neri,
355 2002).

356 The range of uncertainty on the satellite-derived TADR is quite large (of the order of ± 60 %); but no
357 current near-real time (even post-mortem) lava flux rate measurement method is without its
358 problems, and all can have large error of ~ 50 % (Harris et al., 2007). Even the careful, but time-
359 consuming, post-emplacment volumetric measurements made of Etna's 1991-1993 lava flow field
360 Stevens et al. (1997) gave (4 years after the event ended) a mean output rate with an uncertainty of
361 12.5%. Uncertainty and error on TADR measurements is an old problem, which still needs to be
362 addressed. The key challenge remains: how do we make regular, and trusted, TADR measurements
363 in near-real time with uncertainties that are less than 10%? That being said, satellite-derived TADR
364 estimates with 50-60% uncertainty have been proved adequate for tracking effusive events,
365 providing time-series sensitive to real changes in output rate (e.g., Harris et al., 1997a,b; 2000b;
366 2010), so as to provide output of use in a monitoring and modeling role (e.g., Bonaccorso et al., 2015;
367 Vicari et al., 2009; 2011).

368 In the case of Stromboli, validated satellite-derived TADR were particularly useful, in spite of large
369 uncertainty, due to (Harris et al., 2005; Calvari et al., 2007; Lodato et al., 2007):

[Titre du document]

- 370 (i) difficulty and danger of access to the active lava flow field, which was emplaced on a
371 steep slope receiving rock fall and hot grain flow from the collapsing lava flow fronts;
372 (ii) the braided nature of the channel and tube system, and multiplicity of sources;
373 (iii) a lava emplacement mechanism that eroded the loose substrate on which the flows
374 were emplaced so that lava units became embedded in the surrounding terrain – so that
375 thickness measurements were difficult to make; the location of the flow base being
376 impossible to obtain;
377 (iv) lava flow instability, where flows were constantly collapsing into the sea, so that
378 emplaced lava units never remained in place for more than a few hours so that post-
379 mortem field-based area (A) and thickness (h) measurements were impossible – Meaning
380 that TADR derivation from Ah/t , t being duration of unit emplacement were likewise
381 impossible on a regular, operational, basis.

382

383 **TADR tracking using NEODAAS data during effusive crises at Etna and Stromboli**

384 Beginning in 2000, through collaborative agreement with NEODAAS, calibrated, geo-referenced
385 AVHRR channel 3, 4 and 5 brightness temperature data were made available to HIGP for tiles
386 covering Sicily and Iceland (Figure 7). Data were placed on the NEODAAS-Plymouth ftp site upon
387 generation of the brightness temperature image product. A routine running at HIGP checked the ftp
388 site every minute, downloading any new data found. In this way a mirror archive for these two
389 volcanically active zones was built as part of the HIGP hot spot monitoring system.

390 Because no algorithm can be 100% trusted to select all anomalous pixels 100% of the time (Steffke
391 and Harris, 2011), and so as to be sure that all images used were free of cloud contamination, we
392 preferred a manual approach. Also, because only around five images were received each day, the
393 task of image checking and processing was manageable by a human operator. The task was more
394 daunting when using the 96 GOES images received per day by the system for active targets in the
395 GOES footprint; but manageable by an individual charged with maintaining the system. Such a
396 philosophy ensured product quality control and accountability.

397 As described by Moxey et al (2003), operators at HIGP would check the archive at 07:00 am
398 (Hawaiian Standard Time) every morning. All new data would be checked, manually, for cloud cover
399 and presence of a hot spot. The radiances of any hot pixels and their cold background were logged
400 and used to convert to time-averaged discharge rate. For a day's worth of AVHRR data, this process
401 would typically take less than 30 minutes. New vales were appended to a summary table which also

402 contained comments on image quality (e.g., Table 6). This was sent to a controlled email distribution
403 list that involved the main monitoring actors, which included INGV-Catania for eruptions on Etna
404 (Bonaccorso et al., 2015), as well as University of Florence for operations on Stromboli. A hot spot
405 summary table was also maintained (e.g., Table 7). These Tables were appended to a daily up-date
406 email giving, in a standard and consistent format, details regarding the number of images checked,
407 their quality and any TADRs that could be derived (e.g., Table 8).

408 During Etna's 2001 and 2003 eruptions, as well as during Stromboli's 2002-2003 and 2007 eruptions,
409 TADRs were checked against field measurements to allow an assessment of their reliability (e.g.,
410 Figure 8). Results indicated that the empirical conversion applied, that is the x value used in Equation
411 (1), was valid and gave results that agreed with ground-based values (see, for example, Calvari et al.
412 2005; 2010). In addition, the empirical equation of Calvari and Pinkerton (1998) that relates flow
413 length (L) to TADR,

$$414 \quad L = 10^{3.11} \times \text{TADR}^{0.47} \quad (7)$$

415 was applied. For the maximum TADR obtained by AVHRR during Etna's 2001 south flank eruption (30
416 $\text{m}^3 \text{s}^{-1}$), this gave a length of 6370 m and compared with a final length of 6.5 km. During the 2001
417 eruption, this assessment was particularly important because flows were advancing towards the
418 towns of Nicolosi and Belpasso (Figure 9), which lay just a few kilometers further down slope from
419 the flow front (Bonaccorso et al., 2015) and accounted for a total population of 6,959 plus 23,606 for
420 the two population centers, respectively (ISTAT, 2008).

421 Less useful were the 1 km hot spot location maps, because the location of the lava flows was already
422 well-known by ground observers. The maps, though, were posted on the HIGP hot spots web-site
423 (<http://goes.higp.hawaii.edu/goes/etna/>) as soon as data had been received from NEODAAS-
424 Plymouth in case of need. Three of these location maps (in raw, labeled and DEM-merged format)
425 are given in Figure 9, and allow – in spite of the 1 km precision – hot spot location to be assessed in
426 relation to vulnerable locations.

427

428 Stromboli: Operations case-study

429 All eruptions at Etna during the period 2000-2009 were tracked as part of the NEODAAS-HIGP
430 collaboration, and the resulting data base for Etna is given in Harris et al. (2011). No effusive
431 eruption occurred in Iceland over the time period of operations, although two major effusive crises
432 occurred on Stromboli during 2002-2003 and 2007. During the 2002-2003 crisis we were invited, by

[Titre du document]

433 the Italian Civil Protection Department (DPC), to provide methodologies for timely delivery of TADR
434 (Harris et al., 2003). The site conditions, as already discussed, meant that implementation of ground-
435 based methodologies to deliver TADR were difficult-to-impossible. As a result, by May 2003, after
436 five months of effusive activity only one or two field-based measurements of TADR were available.
437 DPC, however, recognized the value of the near-real time TADR metric in tracking the eruption, and
438 so were eager to develop a means of up-dating TADR time-series on at-least a daily basis.

439 Initially, a routine to obtain TADR from thermal camera data obtained during the routine helicopter
440 over-flights made at 09:00 (local time) each morning was developed (Harris et al., 2005). Results
441 were delivered, by 10:00 each morning, to DPC (Harris et al., 2003). In parallel with this, TADR were
442 derived from all available (AVHRR and MODIS) satellite resources and added to the daily report, so as
443 to allow an assessment of whether lava output was stable, increasing or decreasing. During 31 May
444 to 16 June 2003 these were given as power-point presentations each evening at 18:00, during the
445 daily DPC briefing held at the COA (Centro Operativo Avanzato) – the on-site operations center
446 (Bertolaso et al., 2009).

447 Thereafter, the same operation protocol was followed. That is, TADR were prepared on a daily-basis
448 from satellite-flown sensors and then delivered in time for inclusion in daily reporting to DPC. The
449 same protocol was followed during the 2007 crises and involved delivery of TADR reports to
450 members of the Scientific Synthesis Group (SSG). This group was set up under the auspices of DPC
451 (Barberi et al., 2009),

452 “to evaluate the scientific aspects of a volcanic emergency, recommend improvements of the
453 surveillance and provide advise and suggestions to the Civil Protection on the appropriate
454 urgent actions to be undertaken to mitigate risks.”

455 The SSG appointed for the 2007 eruption of Stromboli included groups involved in operational
456 monitoring at Stromboli – mainly from INGV or the University of Florence (UNIFI). These groups
457 were also charged with scientific reporting before, during and after the effusive crisis (Bertolaso et
458 al., 2009). We thus passed information to INGV and UNIFI so as to ensure appropriate injection into
459 the response protocol as given in the flow chart of Bertolaso et al. (2009). Based in this experience,
460 and other interactions with local volcano monitoring agencies around the Pacific Rim (Harris et al.,
461 2002a), we developed the internal protocol charted in Figure 10 for information communication; this
462 preventing crossing of communication lines and protocols set-in place by the responding agencies.

463

464 **Conclusion**

[Titre du document]

465 NEODAAS-Plymouth has extensive expertise in processing satellite data for sea surface temperature
466 and ocean color, as well as near-real time processing of Earth observation data for volcano
467 monitoring. The primary focus is on processing of data from polar orbiting (medium spatial
468 resolution) sensors (~1 km). Product provision focuses on the needs of the UK academic research
469 community, NEODAAS being funded by NERC to support UK research efforts. However, support can
470 be provided to non-UK applications through agreement.

471 In the case followed here, through memorandum of understanding, calibrated, geo-referenced
472 brightness temperature images covering Etna, Stromboli and Iceland were provided in near-real-time
473 for ingestion into the HIGP hot spots system. For the July-August 2001 eruption of Etna, as well as
474 Stromboli's 2007 eruption, event onset was alerted to by the automated detection algorithm linked
475 to a hot spot email notice [see Harris et al (2002a) for notice format]. Veracity of the detection was
476 checked through immediate communication with institutes formally responsible for monitoring Etna
477 and Stromboli who, in turned worked with Civil Protection and were mandated to provide
478 information during eruptive crises. Products were prepared and delivered on a daily basis by 18:00
479 (local – Italian – time). This meant that results when ready for use in daily reporting meetings with
480 Civil Protection, where Bonaccorso et al. (2005) described on-site responses and integration of
481 delivered TADR data into situation appraisals. In this way, dissemination of sensitive data was
482 controlled, allowing information to flow to the source charged with managing the crisis, thereby
483 allowing communication through a single, relevant voice. This followed the dissemination philosophy
484 given in Figure 10. The communication design was also set up so that the recipient, rather than
485 receiving raw data, received fully-processed data that was immediately useable. This was the guiding
486 philosophy of the system: to work with users to provide products, and develop a system, which fitted
487 the user needs, communication protocols and reporting requirements (McArdell, 2002).

760 **Figure Captions**

761 **Figure 1.** (a) coverage of the NEODAAS-Dundee station, and (b) frequency of pass by geographical
762 position within the mask.

763 **Figure 2.** NEODAAS-Plymouth hot spot browser for Etna and Stromboli. The example is from 10
764 March 2013, and hot spots are apparent at Mt. Etna's summit due to effusive and fountaining activity
765 at the SE Crater. In this single-band black-and white rendition, black is cold and white is hot.

766 **Figure 3.** (a) AVHRR channel 4 sub-image of Sicily and Calabria obtained at 00:46Z on 29 May 2001.
767 Sub-image is 320×300 pixels, or $\sim 350 \times 330$ km, in size. Lighter tones indicate higher pixel-
768 integrated spectral radiances. The Aeolian islands of Alicudi, Filicudi, Salina, Lipari, Vulcano, Panarea
769 and Stromboli are labeled using the first letter of each islands name. The oil refinery at, and cape of,
770 Milazzo are located using the red circle (the oil refinery registers a hot spot in the AVHRR MIR and TIR
771 bands). Yellow circle contains an "apparent" hot spot due to the presence of a lake (Biviere di
772 Lentini) which appears relatively warm by night (against the cool land background) and relatively cool
773 by day (against the warm, solar-heated, land background). Note that the real hot spot on Etna is
774 somewhat crisper (more cleanly defined) than the fuzzier "apparent" hot spot of the lake, and two
775 other lake-related "apparent" hot spots can be seen to the SW of Etna. Mount Etna is located using
776 the red box, and is magnified top right. In this nighttime image, the sea (like the lake) is relatively
777 warm (lighter tones) compared with the land (darker tones), and Etna is apparent as a cold, circular,
778 feature (due to its elevation, surface temperatures decrease with height causing the volcano to
779 appear as a cold zone). The hot spot at Etna's summit is centered in the yellow box and magnified
780 lower right. The hot spot is due to pixels containing active lava, and is obvious as a group of hot
781 (white) pixels against a cold (black) background. (b) AVHRR channel 4 sub-image of Sicily and
782 Calabria obtained at 00:36Z on 30 May 2001 (from Electronic Supplement 7 of Harris, 2013).

783 **Figure 4.** Schematic summarizing implementation of the VAST hot spot detection algorithm (from
784 Higgins and Harris (1997, Fig. 3): with permission from Elsevier). The algorithm used three equations
785 a executes five steps.

786 **Figure 5.** Pixel grids of AVHRR channel 4 brightness temperature centered on Mt. Etna's summit hot
787 spot for (a) the 29 May, and (b) the 30 May 2001 sub-images of Figure 3. Values are brightness
788 temperature plus $30\text{ }^{\circ}\text{C}$ multiplied by 100. Area of the anomaly is marked by the red line, with a
789 potential extra "anomalous" pixel in the 30 May being highlighted in yellow. Inclusion of this pixel
790 increases the TADR estimate from $1.7 - 2.1\text{ m}^3\text{ s}^{-1}$ to $2.0 - 2.3\text{ m}^3\text{ s}^{-1}$ (from Electronic Supplement 7 of
791 Harris, 2013).

792 **Figure 6.** Pixel grids of AVHRR channel 4 brightness temperature centered on Mt. Etna’s summit hot
793 spot for (a) the 29 May, and (b) the 30 May 2001 sub-images of Figure 3. Values defined within the
794 hot spot are given in red, and “cold” background pixels are given in blue; these are linked to the
795 “hot” pixels for which they are used to characterize the background spectral radiance in the mixture
796 model using the blue, arrowed, line (from Electronic Supplement 7 of Harris, 2013).

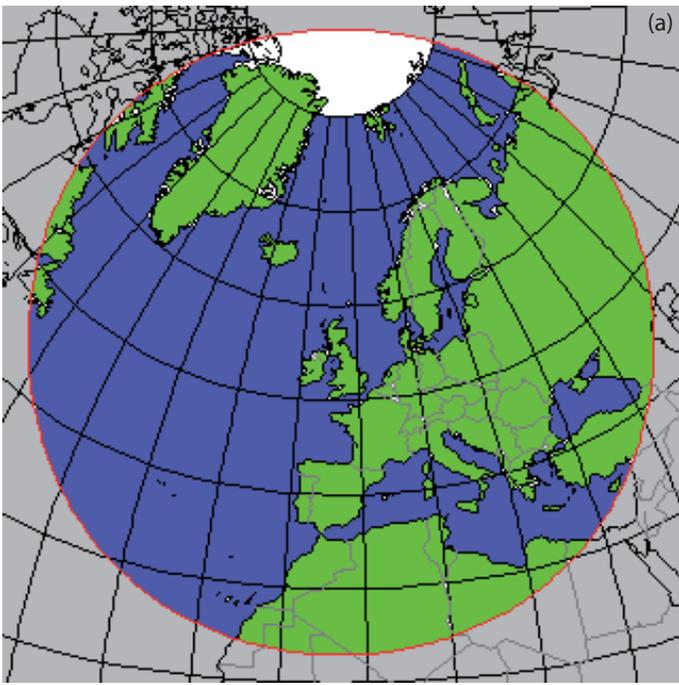

797 **Figure 7.** AVHRR quick look products for (a) the Mt. Etna tile and (b) the Iceland tile; with (c) AVHRR
798 quick look during eruptive activity at Mt Etna in 2001 (AVHRR channel 4 brightness temperature, 22
799 July 2001 15:48 GMT) and (d) MODIS quick look during eruptive activity during 2002 (MODIS top-of-
800 atmosphere true-colour, 28 Oct. 2002 12:15 GMT).

801 **Figure 8.** TADR checks completed during Etna’s 2001 eruption. Field observations were provided by
802 Sonia Calvari (INGV-CT) based on channel dimensions and lava flow velocity upon derivation, field
803 mapping estimates were based on the change in volume of the flow field over 24 hour increments.
804 Lines simply link data points and may not be representative of the actual trend between each linked-
805 point.

806 **Figure 9.** AVHRR channel 4 image of 24 July 2001 (00:58 GMT) showing two hot spots cut by a (cold)
807 plume due to phreatomagmatic activity (Taddeucci et al., 2002; 2004) at the Piano del Lago cone at
808 2500 m (dark is cold; bright is hot). The northern hot spot is due to lava flows from fissures in the
809 summit zone; southern hot spot is due the active lava flow (LSF1) advancing towards Nicolosi and
810 Belpasso. (a) Georeferenced channel 4 image, and (b) fitted to a town and road grid. In addition, the
811 best images were fitted to a DEM of Etna (c). Fit given in (c) is the image for 25 July 2001 at 00:54
812 GMT.

813 **Figure 10.** Response model and flow of data/information through the hot spot response system
814 implemented at HIGP. Example agencies are given on the basis of the Etna 2001 and 2002, as well as
815 the Stromboli 2002-2003 and 2007, experiences. A qualitative assessment of the time delay for data
816 or information provision is indicated at each step. Dashed line is a communication “wall”, where we
817 link into the base of the local communication protocol, where the local communication protocol
818 linked to here is a crude summary of that detailed by Bertolaso et al. (2009) for Stromboli’s 2007
819 effusive crisis.

This week's Brightness Temperature 3

Brightness Temperature 3 Composite

There are no composites for this area

A) ALGORITHM STEPS

Step 1

Create ΔT image (= pixel area within the black box).

Step 2

Define volcano sub-image (= all pixels within the grey box).

Step 3

Apply equations A & B to all pixels in the non-volcanic zone (= all pixels within the black box but outside the grey box) on a pixel by pixel basis. Store the maximum ΔT_{diff} .

Natural variation (ΔT_{nat}) is set equal to maximum ΔT_{diff} .

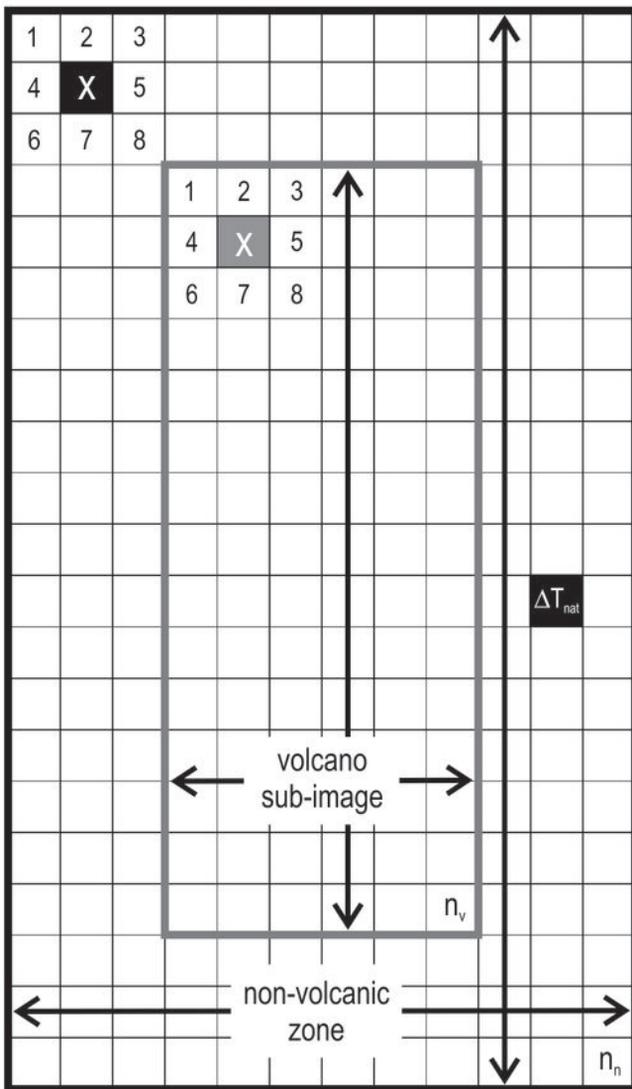

Step 4

Apply equations A, B & C to all pixels in the volcano sub-image on a pixel by pixel basis.

Step 5

Iterate step 4, excluding pixels flagged as "hot" in a previous iteration from equation A, until no new "hot" pixels are found.

B) ΔT IMAGE

n_n = number of pixels in the non-volcanic zone
 n_v = number of pixels in the volcanic sub-image

C) EQUATIONS

Equation A

$$\Delta T_{neigh} = \frac{\sum_{i=1}^8 \Delta T_i}{8}$$

in which $\Delta T_i = \Delta T$ for neighbour pixel i , where $i = 1$ to 8

Equation B

$$\Delta T_{diff} = \Delta T_x - \Delta T_{neigh}$$

in which $\Delta T_x = \Delta T$ for pixel x

Equation C

If $\Delta T_{diff} > \Delta T_{nat}$
 then pixel is "hot"
 else pixel is "cold"

KEY

X Current target pixel in the non-volcanic zone with temperature ΔT_i , where $i = 1$ to n_n

ΔT_{nat} Non-volcanic zone pixel with maximum ΔT_{diff} (= ΔT_{nat})

X Current target pixel in the volcano sub-image with temperature ΔT_i , where $i = 1$ to n_v

Table 1. Studies, and brief details, of AVHRR studies of fire as reviewed by Robinson (1991) [modified from Table 4 of Robinson (1991)].

Study	Details	Reference
Dozier (1980)	Specifications of algorithms to estimate the size and temperature of sub-pixel hot spots using two bands of infrared (AVHRR) data (i.e., definition of the “dual-band method”). Atmospheric correction methods also considered.	<i>NOAA Technical Memorandum, NOAA-81021710</i> , Washington, DC
Dozier (1981)	<i>Ditto</i>	<i>Remote Sensing of Environment</i> , 11 , 221-229.
Matson & Dozier (1981)	The Dozier (1980; 1981) algorithm applied to subpixel hot spots associated with oil flares in the Persian Gulf. Industrial hot spots around Detroit identified.	<i>Photogrammetric Engineering & Remote Sensing</i> , 47 , 1311-1318.
Wan (1985)	Simulation of smoke interference with fire signal reception using multiple scattering radiative transfer model linked to model of AVHRR response.	<i>PhD Dissertation</i> , University of Santa Barbara (CA).
Matson et al. (1984)	Case study of LAC fire imagery described for various sites; fire sightings in western U.S. compared to hot spots appearing in nighttime (2 am) HRPT images	<i>NOAA Technical Report, NESDIS 7</i> , Washington, DC.
Muirhead & Cracknell (1984)	Rectification accuracy tested by comparing hot spot locations on rectified LAC (MIR) images containing gas flare locations of known location and associated with North Sea drilling rigs.	<i>International Journal of Remote Sensing</i> , 5 , 199-212.
Muirhead & Cracknell (1985)	Hot spots counted on three rectified LAC MIR images of U.K. to assess straw burning and extent of compliance with bans on burning on certain days.	<i>International Journal of Remote Sensing</i> , 6 , 827-833.
Malingreau et al. (1985)	Hot spot chronology and NDVI studied of Borneo and East Kalimantan during immense fires of 1983.	<i>Ambio</i> , 14 , 314-315.
Malingreau (1984)	<i>Ditto</i>	<i>8th International Symposium on Remote Sensing of Environment</i> , held in Paris (France), 1-4 October 1984. Ann Arbor: Environmental Research Institute of Michigan.
Flannigan (1985)	Fire reports from severe fire outbreak in Alberta compared to fires detected by AVHRR. Dual-band algorithm used to estimate fire size and temperature. Cloud screening applied to reject cloud contaminated pixels	<i>MSc. Thesis</i> , Colorado State University, Fort Collins (Colorado).
Flannigan & Vonder Haar (1986)	<i>Ditto</i>	<i>Canadian Journal of Forest Research</i> , 16 , 975-982.

Matson & Holben (1987)	Hot spots and vegetation studied on one LAC image for a $3 \times 6^\circ$ box over Manaus, Brazil. Dual-band algorithm applied.	<i>International Journal of Remote Sensing</i> , 8 , 509-516.
Malingreau & Tucker (1987)	Fire points in Southern Amazon Basin studied on a daily basis over two years in conjunction with studies of NDVI. Inference drawn about penetration of settlement into remote areas.	<i>Proceedings of IGARSS '87</i> held in Ann Arbor, Michigan, 18-21 May 1987. IEEE 87CH2434-9 (New York: IEEE), pp. 484-489.
Pereira (1988)	Fire counts and analysis of smoke trajectories with estimates of areas burned and mass combusted based on Brazilian HRPT data of Amazonia. Landsat TM compared to AVHRR.	INPE-4503-tdl/325, Inst. Nacional de Pesquisas Espaciais, 12.201 Sao Jose dos Campos, SP, Brazil.
Setzer et al. (1988)	<i>Ditto</i>	INPE-4534-RPE/565, Inst. Nacional de Pesquisas Espaciais, 12.201 Sao Jose dos Campos, SP, Brazil.

Acronyms:

HRPT: High Resolution Picture Transmission (direct read-out of AVHRR data to ground stations).

GAC: Global Area Coverage.

LAC: Local Area Coverage.

NDVI: Normalized Difference Vegetation Index

[see Cracknell (1997) for full definition of each]

Table 2 Automated fire detection algorithms published in the peer-reviewed literature between 1985 and 1996. Algorithms are listed in chronological order of publication [modified from Harris (2014)]. For more background on algorithm heritage, detail on test set up and execution for each case, see Electronic Supplement 8 of Harris (2013)[§].

Study	Algorithm Type	Tests Executed	Data Type (Application Region)
Flannigan & Vonder Haar (1986)	Contextual	ESTIMATE the mean T_{MIR} and T_{TIR} for cloud-free background pixels from the eight pixels in a 9×9 pixel box centered on the target pixel, then: $T_{MIR-t} > \text{mean } T_{MIR-b}$ $T_{TIR-t} > \text{mean } T_{TIR-b}$ $\Delta T > 8 \text{ K}$ (nighttime); $\Delta T > 10 \text{ K}$ (daytime)	AVHRR (Forest fires – Canada)
Kaufman et al. (1990) ⁽¹⁾	Fixed (Generic)	$T_{MIR} = 316 \text{ K}$ $\Delta T > 10 \text{ K}$ $T_{TIR} > 250 \text{ K}$ (cloud test)	AVHRR (Fires – Brazil)
Lee and Tag (1990)	Contextual	$T_{TIR} < 263 \text{ K}$ (cloud test) Then; ESTIMATE T_{TIR-b} using the mean of the four side pixels in a 9×9 pixel box centered on the target pixel; SELECT a threshold hot component (fire) temperature (T_{fire}) for a two component mixture model and use this, with T_b , to estimate the size of the fire required to yield T_{TIR-t} ; USE T_{fire} , T_{TIR-b} and fire size to estimate the corresponding pixel-integrated temperature in the MIR (T_{thresh}) $T_{MIR} < T_{thresh}$	AVHRR (Wild fires – Yellowstone) (Gas flares – Persian Gulf) (Structure fires – California)
Setzer and Pereira (1991) ⁽²⁾	Fixed (Generic)	$T_{MIR} > 319 \text{ K}$ PLUS: manual detection of smoke	AVHRR (Fires – Brazil)
Brustet et al. (1991)	Fixed (Specific)	MIR and TIR thresholds set manually on a case-by-case basis using frequency distributions and T_{TIR} versus T_{MIR} scatter plots.	AVHRR (Wild fires – West Africa)
Kennedy et al. (1994)	Fixed (Generic)	$T_{MIR} > 320 \text{ K}$ $\Delta T > 15 \text{ K}$ $T_{TIR} > 250 \text{ K}$ (cloud test) and/or $R_{NIR} < 16 \%$ (cloud test)	AVHRR (Wild fires – West Africa)
Langaas (1993)	Contextual	Create frequency distribution of DN_{MIR} ; DN_{MIR} with frequency of 50 = DN_{thresh} IF $DN < DN_{thresh}$ AND $T_{fire}^* > 470 \text{ K}$ THEN	AVHRR (Wild fires – West Africa)

		pixel is anomalous	
Chuvieco and Martin (1994)	Fixed (Generic)	$T_{MIR} > 317$ K (day) $T_{TIR} > 295$ K (night) (applied only within forest mask to reject false detections due to solar heated soil, which could approach saturation).	AVHRR (Forest fires - Spain)
Justice and Dowty (1994)	Contextual (3)	$T_{MIR-t} > 316$ K $T_{TIR-t} > 290$ K $T_{TIR-t} < T_{MIR-t}$ NOW, Target pixel $\Delta T > \Delta T$ mean from the background, plus two times the standard deviation of the ΔT for the background pixels or 3 K (whichever is greater).	Algorithm developed at NASA/Goddard Space Flight Centre
Prins and Menzel (1994)	Contextual	Estimate the mean and standard deviation in T_{MIR} and T_{TIR} for all cloud-free pixels across a 150 km \times 150 km sector. This defines the background values for each band (T_{MIR-b} and T_{TIR-b}); NOW: $\Delta T_t > \text{mean } \Delta T_b$ $T_{MIR-t} - T_{MIR-b} > 1.5 \sigma(T_{MIR-b})$ $T_{MIR-t} > 300$ K and $T_{TIR-t} > 295$ K $T_{TIR-t} - T_{TIR-b} > 1$ K $T_{MIR-t} - T_{MIR-b} > 5$ K $T_{fire}^* > 400$ K	GOES-VAS (Burning – S. America)
Arino and Melinotte (1995)	Fixed (Generic)	$T_{MIR} > 320$ K (saturation test); $T_{MIR} > T_{TIR} + 15$; $T_{TIR} > 245$ K (cloud test); $R_{VIS} < 25$ % (reflection test); $R_{VIS} - R_{NIR} > 1$ % (sunglint test).	AVHRR (Fires – Africa)
Franca et al. (1995)	Fixed (Generic)	$T_{MIR} > 320$ K $\Delta T > 15$ K $T_{TIR} > 287$ K $0 \leq T_{10\mu m} - T_{12\mu m} \leq 5$ K $R_{VIS} < 9$ %	AVHRR (Wild fires – West Africa)
Flasse and Ceccato (1996)	Contextual (3)	$T_{MIR} > 311$ K $\Delta T > 8$ K $T_{MIR} - [\text{mean } T_{MIR-b} - 2\sigma] > 3$ K $\Delta T > [\text{mean } \Delta T_b - 2\sigma]$	

[§] <http://www.cambridge.org/us/academic/subjects/earth-and-environmental-science/remote-sensing-and-gis/thermal-remote-sensing-active-volcanoes-users-manual>

(1) The algorithm was also applied for fire detection in AVHRR data for West Africa by Kennedy et al. (1994).

(2) Another algorithms was published with a similar basis, but using DN criteria (fire if DN < 10 or 8, i.e., if DN are close to AVHRR saturation), by Pereira and Setzer (1993).

(3) Algorithm uses 9 \times 9 pixel box centered on background cleaned of potential fire pixels; box expanded up to limit of 21 \times 21 pixels until at least 25 % of pixels are non-fire.

*estimated using the dual-band method of Dozier (1981).

T_{MIR} = Mid-infrared pixel-integrated temperature; T_{TIR} = Thermal-infrared pixel-integrated temperature;
 $T_{10\mu m}$ = Pixel-integrated temperature at 10 μm ; $T_{12\mu m}$ = Pixel-integrated temperature at 12 μm ;
 T_{MIR-t} = Target pixel MIR brightness temperature; T_{MIR-b} = Background pixel MIR brightness temperature;
 T_{TIR-t} = Target pixel TIR brightness temperature; T_{TIR-b} = Background pixel TIR brightness temperature;
 $\Delta T = T_{MIR} - T_{TIR}$; T_{fire} = sub-pixel fire temperature; T_{thresh} = threshold temperature; σ = standard deviation
 R_{NIR} = Near-infrared reflection; R_{VIS} = Visible reflection; DN = Digital Number (subscripts as per temperatures)

Table 3. Data archiving at NEODAAS-Dundee began in 1978 with the launch of TIROS-N. Today the archive includes data from 10 sensors flown on polar orbiter and geostationary platforms. While a collation of all AVHRR archive data spanning effusive eruptions at Etna are given in Harris et al. (2011); those for Krafla (Iceland) are given in Harris et al. (2000a).

Table 4. Locations of, and average transmissivities, $\tau(\lambda)$, across, the seven main atmospheric windows in the NIR, MIR and TIR (adapted from Harris, 2013). Values obtained using MODTRAN applied using a 1976 US Standard atmosphere with a vertical path from sea-level to space (zenith = 180 °, observer height = 100 km), a CO₂ mixing ratio of 380 ppm·v. In the final column is the range of temperatures (T_{peak}) which have their peak of spectral exitance (λ_m) in the given waveband following re-arrangement of Wien's displacement law, i.e., $T_{\text{peak}} = 2898 \mu\text{m K} / \lambda_m$.

Window Location	Waveband (μm)	Width (μm)	Average $\tau(\lambda)$	Max $\tau(\lambda)$	Location of Max $\tau(\lambda)$ (μm)	T_{peak} (°C)
NIR	0.7 to 0.89	0.19	0.90	0.93	0.89	3900 to 3000
NIR	1.0 to 1.1	0.1	0.94	0.95	1.07	2600 to 2300
SWIR	1.18 to 1.31	0.13	0.94	0.96	1.25	2200 to 1900
SWIR	1.51 to 1.76	0.25	0.96	0.97	1.68	1650 to 1400
SWIR	2.03 to 2.36	0.33	0.96	0.98	2.14	1150 to 950
MIR	3.44 to 4.13	0.69	0.94	0.97	3.96	570 to 430
TIR	8.6 to 12.2	3.6	0.92	0.96	10.11	64 to -35

Table 5. Tests and thresholds used by Harris et al. (2001a) to estimate of hot spot probability. Values output by the algorithm are scaled to 0 to 1, where negative values are mapped to the range 0-0.5 (i.e. 0-50 % probability) and positive values are mapped to the range 0.51-1 (i.e. 51-100 % probability).

Probability step (label)	Test	Description
1 (Prob 1)	Brightness	Pixel albedo ($A1$) is compared with an albedo threshold ($\tau1$) to determine the probability that the pixel is cloud-covered: Bright pixels (i.e., $A1 > \tau1$) are given a positive weighting dependent on the magnitude of the $A1 - \tau1$ difference. Non-bright values (i.e., $A1 < \tau1$) are given a negative weighting dependent on the $A1 - \tau1$ difference.
2 (Prob 2)	Thermal difference	Pixel ΔT radiance is compared with its background (as characterized by the mean of neighboring pixels in a 25×25 pixel box centered on the target pixel = $\Delta TBck$). This provides a measure of the thermal difference between a pixel and its immediate background. If $\Delta T > \Delta TBck$, then the pixel is given a positive weighting dependent on the magnitude of the $\Delta T - \Delta TBck$. Difference. If $\Delta T < \Delta TBck$ then the pixel is given a negative weighting dependent on the magnitude of the $\Delta T - \Delta TBck$ difference.
3 (Prob 2-4)	Thermal anomaly	Pixel ΔT is compared with a ΔT threshold of 10°C (ΔT_{thresh}). This gives a measure of thermally anomalous activity. If $\Delta T > \Delta T_{\text{thresh}}$, then the pixel is given a positive weighting dependent on the magnitude of the $\Delta T - \Delta T_{\text{thresh}}$ difference. If $\Delta T < \Delta T_{\text{thresh}}$, then the pixel is given a negative weighting dependent on the magnitude of the $\Delta T - \Delta T_{\text{thresh}}$ difference.
4 (Prob 4)	Cold test	Pixel TIR brightness temperature (TIR) is compared with a TIR temperature threshold (τTIR), which corresponds to a pixel brightness temperature of -23°C . This gives a measure of how cold the pixel is, and thereby the probability that cold cloud is present. If $TIR > \tau TIR$, then the pixel is given a positive weighting dependent on the magnitude of the $TIR - \tau TIR$ difference. If $TIR < \tau TIR$, then the pixel is given a negative weighting dependent on the magnitude of $TIR - \tau TIR$ difference.
Total probability (PROB)	PROB = Prob 1 \times Prob 2 \times Prob 3 \times Prob 4	Total probability is the product of the 4 sub-probabilities (Prob 1 to 4) and is therefore designed to provide a quantitative assessment of whether a pixel (1) contains cloud, (2) is thermally different from its background, and (3) is thermally anomalous.

Table 6. AVHRR-derived TADR log built during Etna's 2001 flank eruption.

Table 7. Activity time-line and AVHRR observations for Etna during July 1 – 18, 2001.

Date	Ground-based observations (INGV-Catania)	AVHRR-based observations
July 1-4	No glow observed (last paroxysm from SEC was ~23:00 (6/29) - ~21:00 (6/30))	1-3 pixel, low magnitude hot spots @ SEC
July 4	11:00: lava effusion begins @ SEC 22:30: Increase in Strombolian activity 00:45: Activity declining (07/5)	8 pixel, high magnitude hot spot @ SEC
July 7-17	Continuous lava flow effusion from SEC	AVHRR hot spot steadily increases in size and magnitude: 7/07 = 2 pixels 7/11 = 3 pixels 7/15 = 6 pixels
July 9	Episode of mild strombolian activity @ SEC (early)	AVHRR = cloud covered
July 13	Paroxysm @ SEC (early am)	01:19 GMT image shows 3 pixel, high magnitude hot spot at SEC
July 17	Paroxysms @ SEC in early am, in the following hours fissures open at the S. base of SEC and extend S. These feed strombolian & lava flow activity	00:37 GMT image shows 16 pixel, high magnitude anomaly @ SEC with plume extending ENE. 12:13 GMT image shows high magnitude hot spot between SEC and Montagnola
July 17	Second fissure becomes active on N flank of Montagnola. Flows begin to extend away from eruptive fissure. Over the following days these flow extended S to threaten the ski area and Sapienza complex	
July 18	~02:00 (local time) 2100 m vent begins activity. Over following days flows from this vent extend S towards Nicolosi	12:03 GMT image shows first dual hot spot, with hot spot #1 between SEC and Montagnola, & #2 below Montagnola (2100 m vent)
July 18	Main vent on N flank of Montagnola opens up: becomes source of major ash emissions	
July 20	Flow active from NE extending fissure segment, flows extend into Valle del Leone	Activity apparent as third hot spot to NE of SEC especially on July 22-23 images

Table 8. Email notices sent out between 19 March and 9 April during Stromboli's 2007 eruption.

<p>To: Distribution list Re: Stromboli: 19-28 March 2007</p>
<p>Complete or partial cloud cover meant that no AVHRR-based TADR estimates were possible during 18-25 March (although the anomaly was observed through or between clouds on 10 occasions).</p> <p>Since 26 March cloud conditions have improved allowing TADR estimates from 5 of the 14 passes over the last 3 days. These give the following TADRs:</p> <p>26 March 07 – 09:54 UT – 0.9 – 1.4 m³/s 26 March 07 – 12:21 UT – 0.7 – 1.6 m³/s 27 March 07 – 21:00 UT – 0.7 – 1.7 m³/s 28 March 07 – 12:01 UT – 0.7 – 1.6 m³/s 28 March 07 – 20:37 UT – 0.5 – 1.4 m³/s</p>
<p>To: Distribution list Re: Stromboli: 28 March – 3 April 2007</p>
<p>Complete or partial cloud cover meant that no AVHRR-based TADR estimates were possible during 29 & 30 March.</p> <p>Since the afternoon of 31 March cloud conditions have improved allowing TADR estimates from 4 passes spanning 31 March – 2 April. These give the following TADRs:</p> <p>31 March 07 – 21:08 UT – 0.5 – 1.3 m³/s 01 April 07 – 01:24 UT – 0.4 – 0.9 m³/s 01 April 07 – 20:45 UT – 0.9 – 2.2 m³/s 02 April 07 – 12:50 UT – 0.6 – 1.3 m³/s</p> <p>As of 3 April, cloud conditions had deteriorated again such that all 5 of today's images were cloud covered.</p>
<p>To: Distribution list Re: Stromboli: 3-9 April 2007</p>
<p>Although we've looked at data from 34 passes during 3-9 April, cloud (sometimes localized but just sitting right over Stromboli) has meant that we have had no data suitable for TADR calculation since 2 April.</p> <p>We did see a band 3 hot spot on 5 occasions in this period, but they all appeared cloud contaminated and there was no convincing band 4 anomaly.</p>
